APPLICATION OF RADIOACTIVE INDICATORS IN BIOLOGY[1]

By G. Hevesy

Institute for Theoretical Physics,
The University, Copenhagen, Denmark

Natural radioactive isotopes of some of the heaviest elements are easily available and labelled lead, bismuth, and thorium were used in biological research at an early date. The circulation of lead in plants (1) and that of lead, bismuth, and thorium in both normal (2, 3) and carcinomatous (4) animals was investigated by this method. Extended use was made of radioactive bismuth in the study of the rate of absorption of the various bismuth preparations used in syphilis therapy (5). The discovery of artificial radioactivity and the rapid and successful development following this important event (6) made it possible to obtain "artificial" radioactive isotopes of numerous elements and opened thus a vast field for the application of isotopic indicators in biology. Among the elements of biological importance, hydrogen has no radioactive isotope, while nitrogen, oxygen, and carbon have such short half lives that their application for most purposes is excluded, though the radioactive isotope of carbon has met with some very useful applications (see pp. 658, 659). The discovery of heavy hydrogen and the recent progress (7) in the separation of the isotopes of oxygen, nitrogen, and carbon have made it possible to make use of labelled hydrogen, nitrogen, oxygen, and carbon, the tagged elements being identified by density measurements and mass-spectrographic determinations respectively. No fundamental difference is to be found between the application of radioactive and of stable isotopes as indicators. To limit the scope of discussion, however, it may be preferable to treat the application of radioactive indicators separately from that of the nonradioactive ones. In what follows, we will first discuss the use of radioactive phosphorus for labelling purposes. This isotope has found so far the most extensive application; furthermore, in view of its importance both in the study of inorganic and of organic metabolism, its application presents very suitable examples of the type of problems which can be successfully attacked by the use of tagged elements.

Residual Mass in Lymphoma May Not Be Residual Disease

The report of Radford et al[6] illustrates two important points in the assessment of patients following any therapy for Hodgkin's disease. First, residual masses in the mediastinum may not represent residual disease since only 18% of their patients with residual abnormalities ever relapsed. Second, the presence of residual radiographic abnormalities might render a patient as a partial or incomplete responder, and thus may be an inaccurate measure of the efficacy of a particular treatment. In the Radford et al series, 45% of patients considered to have incomplete mediastinal remissions eventually achieved a complete remission in a period of 1 year. This suggests that immediate posttherapeutic assessment of extent of response may erroneously judge a treatment as achieving only a partial remission.

Radionuclide scans have had a mixed acceptance as a staging tool in the past. The use of high-dose (10 mCi) gallium 67 citrate (^{67}Ga) and improved gamma camera detection, as well as single photon emission CT (SPECT) scans have considerably improved the sensitivity of the technique.[16] A retrospective analysis at the DFCI of ^{67}Ga uptake following combination chemotherapy (four cycles) for large-cell lymphoma identified patients likely to relapse when avidity for ^{67}Ga was still present regardless of radiographic appearance.[17] This approach may prove to be the most useful test yet for the identification of viable residual disease in lymphoma.

Gallium-67 Imaging: A Predictor of Residual Tumor Viability and Clinical Outcome in Patients With Diffuse Large-Cell Lymphoma

Use of Positron Emission Tomography for Response Assessment of Lymphoma: Consensus of the Imaging Subcommittee of International Harmonization Project in Lymphoma

Malik E. Juweid, Sigrid Stroobants, Otto S. Hoekstra, Felix M. Mottaghy, Markus Dietlein, Ali Guermazi, Gregory A. Wiseman, Lale Kostakoglu, Klemens Scheidhauer, Andreas Buck, Ralph Naumann, Karoline Spaepen, Rodney J. Hicks, Wolfgang A. Weber, Sven N. Reske, Markus Schwaiger, Lawrence H. Schwartz, Josee M. Zijlstra, Barry A. Siegel, and Bruce D. Cheson

RECOMMENDATIONS

1. Use of PET for Response Assessment of Lymphoma at the Conclusion of Therapy

Numerous studies have demonstrated the value of PET or PET/CT for response assessment of HL and diffuse large B-cell NHL (DLBCL) at the conclusion of front-line, salvage, or high-dose therapy.[5-16] Based on the meta-analysis by Zijlstra et al,[5] pooled sensitivity and specificity of FDG-PET for detection of residual disease after completion of first-line therapy were 84% (95% CI, 71% to 92%) and 90% (95% CI, 84% to 94%), respectively, for HL, and 72% (95% CI, 61% to 82%) and 100% (95% CI, 97% to 100%), respectively, for aggressive NHL. Accurate information regarding tumor status after treatment of these lymphoma subtypes is critical because these are curable lymphomas. The value of PET in this setting is its ability to distinguish between viable tumor and necrosis or fibrosis in residual masses often present after treatment in patients without any other clinical or biochemical evidence of disease.[6-17] Conventional anatomic imaging modalities generally are unable to make this distinction because the morphologic features of these tissues are usually indistinguishable. False-positive PET findings at the site of residual masses can be seen, however, and have been discussed in detail by Juweid and Cheson,[1,2] among others.

The role of PET for response assessment of aggressive NHL subtypes other than DLBCL and of indolent and mantle-cell lymphomas, is less clear. For these generally incurable NHLs, progression-free or overall survival is usually the primary end point in clinical trials evaluating their response to treatment.[18] However, if overall objective response rate and, particularly, complete response rate are major end points in certain clinical trials, PET may be used for their more accurate determination.[18]

Monitoring Primary Systemic Therapy of Large and Locally Advanced Breast Cancer by Using Sequential Positron Emission Tomography Imaging With [^{18}F]Fluorodeoxyglucose

Jörg Schwarz-Dose, Michael Untch, Reinhold Tiling, Stefanie Sassen, Sven Mahner, Steffen Kahlert, Nadia Harbeck, Annette Lebeau, Winfried Brenner, Markus Schwaiger, Fritz Jaenicke, and Norbert Avril

Conclusion

FDG-PET allows for prediction of treatment response by the level of FDG uptake in terms of SUV at baseline and after each cycle of chemotherapy. Moreover, relative changes in SUV after the first and second cycle are a strong predictor of response. Thus, FDG-PET may be helpful for individual treatment stratification in breast cancer patients.

Positron Emission Tomography Is Superior to Computed Tomography Scanning for Response-Assessment After Radical Radiotherapy or Chemoradiotherapy in Patients With Non–Small-Cell Lung Cancer

By Michael P. Mac Manus, Rodney J. Hicks, Jane P. Matthews, Allan McKenzie, Danny Rischin, Eeva K. Salminen, and David L. Ball

Journal of Clinical Oncology, Vol 21, No 7 (April 1), 2003: pp 1285-1292

Results: **Median survival after follow-up PET was 24 months. There was poor agreement between PET and CT responses (weighted kappa = 0.35), which were identical in only 40% of patients. There were significantly more complete responders on PET (n = 34) than CT (n = 10), whereas fewer patients were judged to be nonresponders (12 patients on PET *v* 20 on CT) or nonassessable (zero patients on PET *v* six on CT) by PET. Both CT and PET responses were individually significantly associated with survival duration; but on multifactor analysis that included the known prognostic factors of CT response, performance status, weight loss, and stage, only PET response was significantly associated with survival duration ($P < .0001$).**

Conclusion: **In NSCLC, a single, early, posttreatment PET scan is a better predictor of survival than CT response, stage, or pretreatment performance status.**

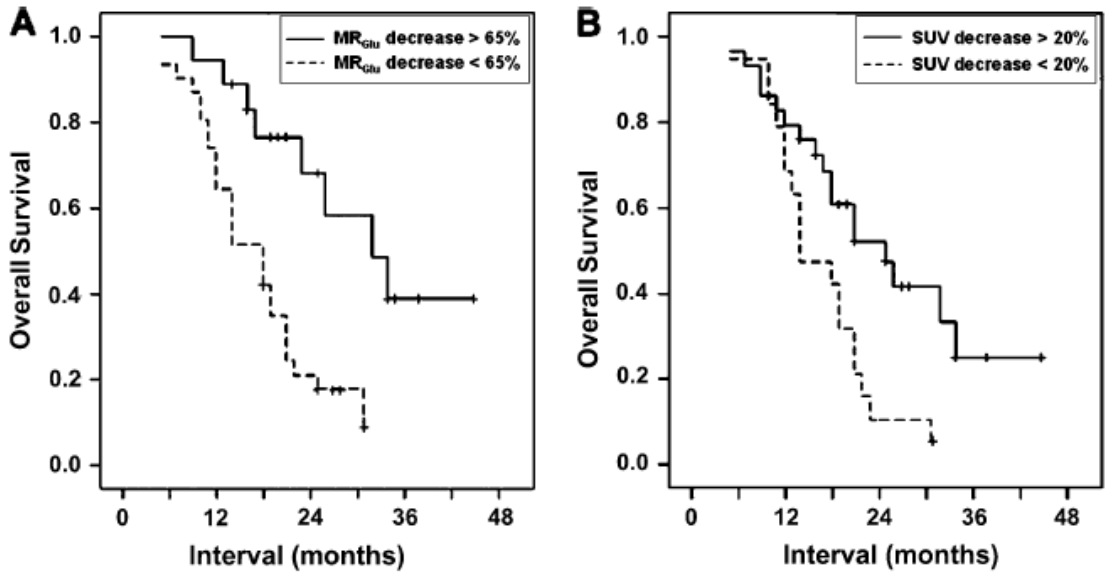
Chemotherapy response evaluation with FDG–PET in patients with colorectal cancer

L. F. de Geus-Oei[1]*, H. W. M. van Laarhoven[2], E. P. Visser[1], R. Hermsen[1], B. A. van Hoorn[1], Y. J. L. Kamm[2], P. F. M. Krabbe[3], F. H. M. Corstens[1], C. J. A. Punt[2] & W. J. G. Oyen[1]

Annals of Oncology 19: 348–352, 2008



Conclusion: The degree of chemotherapy-induced changes in tumor glucose metabolism is highly predictive for patient outcome. The use of FDG–PET for therapy monitoring seems clinically feasible since simplified methods (SUV) are sufficiently reliable.

Monitoring and Predicting Response to Therapy with ^{18}F-FDG PET in Colorectal Cancer: A Systematic Review

Lioe-Fee de Geus-Oei[1], Dennis Vriens[1], Hanneke W.M. van Laarhoven[2], Winette T.A. van der Graaf[2], and Wim J.G. Oyen[1]

[1]*Department of Nuclear Medicine, Radboud University, Nijmegen Medical Centre, Nijmegen, The Netherlands; and*
[2]*Department of Medical Oncology, Radboud University, Nijmegen Medical Centre, Nijmegen, The Netherlands*

CONCLUSION

Published data indicate that ^{18}F-FDG PET has a high predictive value in the therapeutic management of colorectal cancer. This technique could be an asset for improving patient care by reducing the effort, costs, and morbidity associated with ineffective treatment in nonresponders. The available studies on chemotherapy response monitoring in advanced colorectal cancer and on preoperative radiotherapy and multimodality treatment response evaluation in primary rectal cancer indicate that ^{18}F-FDG PET is a significant predictor of therapy outcome in both situations. In primary rectal cancer, ^{18}F-FDG PET is

Special Paper

Can Positron Emission Tomography (PET) be Used to Detect Subclinical Response to Cancer Therapy?

P. Price and T. Jones on behalf of the EC PET Oncology Concerted Action and the EORTC PET Study Group

At the EORTC NCI New Drug Development Meeting in Amsterdam in 1994, a workshop, suggested by the EC PET (positron emission tomography) Oncology concerted action, was held to bring together many of those European PET centres investigating the use of [^{18}F]FDG ([^{18}F]2-fluoro-2 deoxyglucose) PET scanning as a measure of response to cancer therapy. Of the current 31 PET centres in Europe invited to contribute, 15 centres already had data and others expressed interest. Many of the groups were collaborating with local oncologists to measure tumour response to chemotherapy (12 groups) and radiotherapy (three groups) with this technique. Despite variations of methodology, and difficulties in data interpretation, assessment of tumour [^{18}F]FDG uptake was thought to be a reasonable method for the functional imaging of tumours, assessing metabolic rate and providing a measure of tumour response. Broadly, pooling experience, it would appear that changes in [^{18}F]FDG tumour uptake following one or two cycles of chemotherapy treatment was related to ultimate clinical responses. Patients showing most reduction in [^{18}F]FDG uptake achieved the best clinical responses. Data were also available on the effect of chemotherapy on normal tissues and some data on the effect of radiotherapy and tumour response. It was concluded that changes in [^{18}F]FDG uptake as measured with PET may provide useful information on clinical as well as subclinical response of tumours to anticancer therapy. This could be useful as a guide to early response to therapy as well as providing functional assessment of residual masses of disease. More specific markers of cellular proliferation e.g. [^{11}C]thymidine, or [^{11}C]- amino acids may provide even more accurate information. A strategy was outlined whereby PET scanning protocols could parallel EORTC early clinical trials so that [^{18}F]FDG response information could supplement phase I and II clinical studies. Following these developments, an EORTC study group was formed under the auspices of the EORTC research branch, and the strategy for future development in Europe outlined.

From RECIST to PERCIST: Evolving Considerations for PET Response Criteria in Solid Tumors

Richard L. Wahl[1,2], Heather Jacene[1], Yvette Kasamon[2], and Martin A. Lodge[1]

May 1 2009, Volume 50, Suppl_1

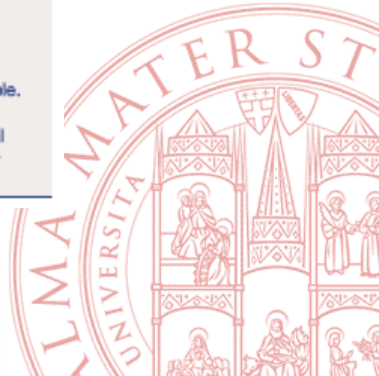
Introduction to PERCIST 1.0

Based on the extensive literature now supporting the use of ^{18}F-FDG PET to assess early treatment response as well as the known limitations of anatomic imaging, updated draft PET criteria are proposed that may be useful for consideration in clinical trials and possibly clinical practice. We have called these draft criteria "PERCIST"—Positron Emission tomography Response Criteria In Solid Tumors. The RECIST committee did not have a role in developing these criteria, but while we were developing them we acknowledged and appreciated the careful work and approaches of the RECIST committee. We also recognized that, as with RECIST, criteria such as PERCIST will need updates and validation in differing settings. With apologies to the RECIST group, we believed that the name *PERCIST* seemed quite appropriate as a complement to the well-developed anatomic criteria now in widespread use and recently updated.

EORTC

PERCIST

Characteristic	EORTC	PERCIST 1.0
	PMR: reduction of minimum of 15% ± 25% in tumor ^{18}F-FDG SUV after 1 cycle of chemotherapy, and >25% after more than 1 treatment cycle; reduction in extent of tumor ^{18}F-FDG uptake is not a requirement for PMR.	PMR: reduction of minimum of 30% in target measurable tumor ^{18}F-FDG SUL peak. Absolute drop in SUL must be at least 0.8 SUL units, as well. Measurement is commonly in same lesion as baseline but can be another lesion if that lesion was previously present and is the most active lesion after treatment. ROI does not have to be in precisely same area as baseline scan, though typically it is. No increase, >30% in SUL or size of target or nontarget lesions (i.e., no PD by RECIST or IWC) (if PD anatomically, must verify with follow-up). Reduction in extent of tumor ^{18}F-FDG uptake is not requirement for PMR. Percentage decline in SUL should be recorded, as well as (ideally) time in weeks after treatment was begun (i.e., PMR −40, 3). No new lesions.
	SMD: increase in tumor ^{18}F-FDG SUV < 25% or decrease of <15% and no visible increase in extent of ^{18}F-FDG tumor uptake (20% in longest dimension).	SMD: not CMR, PMR, or PMD. SUL peak in metabolic target lesion should be recorded, as well as (ideally) time from start of most recent therapy, in weeks (i.e., SMD −15, 7).
	PMD: increase in ^{18}F-FDG tumor SUV of >25% within tumor region defined on baseline scan; visible increase in extent of ^{18}F-FDG tumor uptake (20% in longest dimension) or appearance of new ^{18}F-FDG uptake in metastatic lesions.	PMD: >30% increase in ^{18}F-FDG SUL peak, with >0.8 SUL unit increase in tumor SUV peak from baseline scan in pattern typical of tumor and not of infection/treatment effect. OR: Visible increase in extent of ^{18}F-FDG tumor uptake (75% in TLG volume with no decline in SUL. OR: New ^{18}F-FDG–avid lesions that are typical of cancer and not related to treatment effect or infection. PMD other than new visceral lesions should be confirmed on follow-up study within 1 mo unless PMD also is clearly associated with progressive disease by RECIST 1.1. PMD should be reported to include percentage change in SUV peak, (ideally, time after treatment, in weeks) and whether new lesions are present/absent and their number (i.e., PMD, +35, 4, new: 5). Because SUL is continuous variable, dividing response criteria into limited number of somewhat arbitrary response categories loses much data. For this reason, PERCIST preserves percentage declines in SUV peak in each reported category. Because rapidity with which scan normalizes is important (faster appears better), PERCIST asks for time from start of treatment as part of reporting. For example, CMR 90, 1, is probably superior to CMR 90, 10, especially if latter patient were SMD 20, 1. More than one measurement of PET response may be needed at differing times, and it may be treatment type–dependent. PERCIST 1.0 evaluates SUL peak of only hottest tumor. This is possible limitation of approach, but lesions and their responses are highly correlated in general. Additional data are required to determine how many lesions should be assessed over 1. A suggested option is to include the 5 hottest lesions, or the 5 observed on RECIST 1.1 that are most measurable. Percentage change in SUL can be reported for single lesion with largest increase in uptake or smallest decline in uptake. Additional studies will be needed to define how many lesions are optimal for assessment.



EORTC

criteria for evaluating metabolic response to therapy using FDG PET:

- **CR:** same metabolic rate as normal tissue
- **PR:** after I cycle 15-25% decrease in SUV
  after II cycle > 25% decrease in SUV
- **PD:** > 25% increase of SUV or apparence of new lesions
- **SD**: difference of –15% to +25% in SUV ; same extension

Variations in PET/CT Methodology for Oncologic Imaging at U.S. Academic Medical Centers: An Imaging Response Assessment Team Survey

THE JOURNAL OF NUCLEAR MEDICINE • Vol. 52 • No. 2 • February 2011

Michael M. Graham[1], Ramsey D. Badawi[2], and Richard L. Wahl[3]

CONCLUSION

A survey applied mainly to academic PET centers participating in the IRAT network showed considerable variability in patient preparation, ^{18}F-FDG dose, CT technique, tracer uptake, imaging time, reconstruction methods, and suitability of PACS for PET/CT display. The existence of this variance despite professional guidelines suggests that results from quantitative PET analyses are likely to differ widely across centers. These data indicate that additional standardization is needed to bring about results—particularly quantitative results—that are more comparable among sites.

Prediction of Response to Neoadjuvant Chemotherapy by Sequential F-18-Fluorodeoxyglucose Positron Emission Tomography in Patients With Advanced-Stage Ovarian Cancer

Tumor-Specific Positron Emission Tomography Imaging in Patients: [^{18}F] Fluorodeoxyglucose and Beyond

David A. Mankoff, Janet F. Eary, Jeanne M. Link, Mark Muzi, Joseph G. Rajendran, Alexander M. Spence, and Kenneth A. Krohn

Clin Cancer Res 2007;13(12) June 15, 2007

Biochemical and molecular imaging of cancer using positron emission tomography (PET) plays an increasing role in the care of cancer patients. Most clinical work to date uses the glucose analogue [^{18}F]fluorodeoxyglucose (FDG) to detect accelerated and aberrant glycolysis present in most tumors. Although clinical FDG PET has been used largely to detect and localize cancer, more detailed studies have yielded biological insights and showed the utility of FDG as a prognostic marker and as a tool for therapeutic response evaluation. As cancer therapy becomes more targeted and individualized, it is likely that PET radiopharmaceuticals other than FDG, aimed at more specific aspects of cancer biology, will also play a role in guiding cancer therapy. Clinical trials designed to test and validate new PET agents will need to incorporate rigorous quantitative image analysis and adapt to the evolving use of imaging as a biomarker and will need to incorporate cancer outcomes, such as survival into study design.

Conventional and novel PET tracers for imaging in oncology in the era of molecular therapy

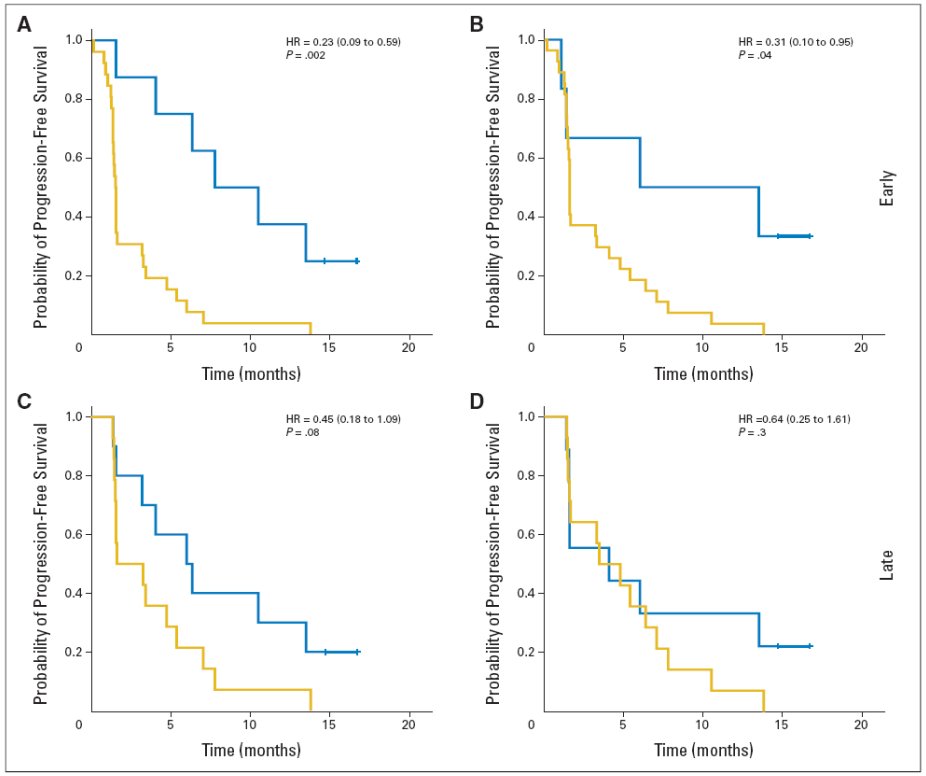

Fig 3. Early reduction in (A) 2′-deoxy-2′-[^{18}F]fluoro-D-glucose FDG and (B) 3′-[^{18}F]fluoro-3′-deoxy-L-thymidine (FLT) uptake is associated with longer progression-free survival. Late reduction in (C) FDG and (D) FLT positron emission tomography is not associated with progression-free survival. A cutoff of ≥ 30% reduction in standardized uptake value peak (SUV_{peak}) was used for classifying patients. Blue lines, metabolic response; gold lines, nonmetabolic response. HR, hazard ratio.

Pharmacodynamic Study Using FLT PET/CT in Patients with Renal Cell Cancer and Other Solid Malignancies Treated with Sunitinib Malate

Clin Cancer Res; 17(24) December 15, 2011

In summary, we have shown that during sunitinib treatment on both the 4/2 and 2/1 schedules, there are statistically significant increases in median sunitinib concentrations and median serum VEGF levels, and a median decrease in cellular proliferation as measured by SUV_{mean} and SUV_{max}. Change in VEGF during sunitinib treatment predicted change in SUV_{mean} during sunitinib withdrawal, which fits with the biologically plausible hypothesis that the rise in VEGF ligand during treatment may drive tumor flare during the withdrawal period. Finally, there was a suggestion of a more brisk proliferative flare in nonresponders compared with responders. This suggests that patients with a robust compensatory response to treatment-induced hypoxia (e.g., large flare) might develop early treatment failure as a result.
